## ACKNOWLEDGEMENTS

#### Abstract

The author wishes to express a special thanks to some of the people who helped in the completion of this thesis:

To Dr. John N. Cernica, who served as thesis advisor, provided guidance, discussed and reviewed the progress of the thesis;

To the Civil Engineering Faculty and especially to Dr. Richard A. Mirth and Dr. J.D. Bakos who provided input during the planning and testing phase of the study';

To The Standard Slag Company who provided most of the materials for the construction of the specimens;

To my parents who encouraged me to enter the field of Civil Engineering;

A special word of appreciation to Miss Debbie Campanizzí, who typed this manuscript.

#### Abstract

The scope of this thesis was to determine the difference in concrete strength from using two different aggregates, crushed and uncrushed. The surface texture of the aggregate used is the primary factor that influences the strength of the mortaraggregate bond. In this attempt the thesis has been divided in two parts.

The first part deals with laboratory work done by the author. One hundred fifty-six specimens were constructed. The specimens were then tested under compression loading.

The second part of this thesis analyzed the data obtained in the laboratory, through the useofstatistical methods.

The results demonstrate that the use of crushed aggregate increases the concrete strength by approximately ten per cent over the use of uncrushed.

## INTRODUCTION

Research studies ${ }^{4}$ have indicated that the mortar-aggregate bond influences the strength and deformation of concrete. However, such effects are not easy to observe experimentally due to difficulties involved in isolating bond strength as a single aggregate variable. The principal approach has been via the use of aggregate coatings and some early studies on that reported very large decreases in the compressive strength of concrete. Studies done by Kaplan ${ }^{2}$ show that the shape and texture of the aggregate are particularly significant in the case of high strength concrete. Although the full role of shape and texture of the aggregate in the development of concrete is not known, the consensus is that a rougher texture results in a greater adhesive force between the particles and cement matrix.

The approach used by the author was throuqh the construction and testing of six sets of specimens. Each set consisted of twenty-six specimens, one half of those made with crushed aggreqate and the other half with uncrushed."* The primary factor used in developing the concrete strength in each set was throuqh the variation of the water-cement ratio.

The data from these tests were analyzed using statistical methods in order to find the percent difference between the mean values of the two groups in each set.

[^0]** The aggregate was essentially the same river gravel, except one was crushed and the other uncrushed. However, the soundness of the two types of aggreqate was not taken into account.

## CHAPTER I

## EXPERIMENTAL PROCEDURE

## 1.1

1.2

## Objective

One hundred fifty-six specimens were constructed with two different types of aggregate and tested under compression loading.

The author realizes that testing only one hundred fiftysix specimens would not encompass all variables. Thus, the conclusions and recommendations made from these experiments are of limited value. Hence, it is advisable that more specimens should be made and additional testing done.

## Concrete Mix:

Since the ultimate goal was to compare the effects on concrete strength resulting from the use of two different types of aggregates (crushed and uncrushed), the mix proportion was purposely kept constant throughout each set of specimens.

The concretemixes were designed for an interval of compressive strengths from 3000 to 5500 psi and average density of 130-145 lb. per cubic ft. The following materials were used:
a) Ordinary Portland Cement Type I
b) Gravel (crushed and uncrushed) as an aggregate
c) Natural Sand with specific gravity of 2.62

The effective absorptions of the crushed and uncrushed gravels used were $2.84 \%$ and $1.54 \%$ respectively. The average size of coarse gravel was one-half inch. The figures that follow show the crushed and uncrushed gravel.

Step 5. Then the mixture containing the gravel and one third of the water was added into the mixer and all the ingredients were mixed together for an additional three minutes, followed by three minutes rest, followed by two minutes final mixing.

The top of the mixer was covered at all times in order to prevent any loss of fines while mixing and evaporation during the rest period. In order to eliminate segregation the machine-mixed concrete was deposited in a clean, damp mixing pan and remixed manually by a shovel until it appeared to be uniform.

### 1.4 Making the specimens:

Using the same trial mixes as previously discussed it was found that the most reliable way of placing the concrete into the molds was as follows:

The concrete was placed into the molds through the use of a scoop, and each scoopful of concrete was selected in such a way that it was a good representation of the batch. The concrete in each mold was placed in-three equal layers and each layer compacted 25 times using a end-rounded rod $5 / 8^{\prime \prime}$ in diameter.
1.5 Curing the specimens:

The specimens were removed from the molds 36 hours after castingand cured in saturated lime water for 27 days. The specimens were then removed from the water, capped and tested. Figures 2, 3, and 4 show sets 1
and 2 ready to be tested, sets 3 and 4 just after they were capped and sets 5 and 6 in the molds respectively. The temperature of the curing water was maintained at $72^{\circ} \ddagger \pm 1^{\circ}$.

Figure 2 Sets 1 and 2 ready to be tested.
1.6 Proportions of ingredients:

The proportions of the ingredients for each set of concrete mix were selected based purely on the strength desired. In order to achieve different strengths, the. water to cement ratio was varied. This was accomplished by keeping the aggregate content constant and varying the cement and the water content, in order to achieve a workable mix. At the same time the sand content was varied in order to keep the total weight of each set of concrete m1x constant.

Tables 1 through 6 show the proportions of the ingredients
used for each set of concrete mix.

### 1.7 Testing the specimens:

The specimens were tested 28 days after casting. Figure 5 shows a specimen ready to be tested under the 250,000 pound Formey Concrete Compression Tester. The testing machine is motorized and the loading rate that was used was approximately 35 psi/min. which is within the limits of ASTM Designation C 39-66.1 Figure 6 shows the same specimen after failure.

Tables 7 through 18 show the ultimate loads and corresponding stresses for each set.

Figure 3 Sets 3 and 4 just after they were capped.

## 2.1

## Introduction

Therearemany factors which are involved in the production of high quality concrete: materials, quality proportioning, handling and placing, curing and testing. It should, therefore, come as no surprise that concrete, in common with some engineering materials, is inherently not a homogeneous and isotropic material.

The data from the' laboratory work substantiatesthis observation. Hence, in order to find the difference in strength between crushed and uncrushed aggregate some statistical methods were used.
2.2

Statistical methods used for analysis
In order to estimate the magnitude of difference between the respective means of the two groups in each set, the following equation was used (see Ref. 3):

where:

$$
\begin{aligned}
& \text { (Xa) or }(X b)=\frac{x l+x 2+x 3+. . . . . . . x i}{n} \\
& \text { and } n-\text { Total number of specimens in the group } \\
& \quad X a-M e a n \text { of qroup } A \\
& \quad X b-M e a n \text { of qroup } B \\
& \left(s a^{2}\right) \text { or }\left(s b^{2}\right)=\frac{(x l-X)+(x 2-X)+(x 3-X)+\ldots(x i-x)}{n-l} \\
& \text { and sa }- \text { Sample variance in group } A
\end{aligned}
$$

sb - Sample variance in group B
X - Xa or Xb (depends on the group)
i - From 1 to 13
na - Sample size in group A
nb - Sample size in group B
ma-mb - Confidence interval for the difference between means using small independent samples.
ta/2 - Value taken from table A for na+nb-2
degrees of freedom.

Also in order to calculate the t-distribution with
2(n-1) degrees of freedom the following equation was'used (Ref.3):

In order to calculate ma-mb and the $t$-distribution for each set, a computer program was made using equations (1) and (2) (see pg. 13) and the results from it are shown on Page 33.

> PROGRAM - Watfiv program using equations (1) and (2).

2.3 Discussion and evaluation of results

In order to evaluate the results from WATFIV program, four different graphs were plotted.

In graph 1 the "stress" vs. "w/c ratio" was plotted using the method of least squares. From this graph it can be observed that the influence of the coarse aggregate on the strength of concrete varies in magnitude and depends on the water/cement ratio of the mix. For water/cement ratios of about 0.4 , the use of crushed gravel resulted in strengths of about 10 percent higher than for the uncrushed. As water/cement ratios increase, of about $0.65-0.70$, only a relatively small difference in the strengths of the concrete made with either crushed or uncrushed gravel were observed. With an increase in water/cement ratio, the influence of the type of crushed gravel, decreased, presumably because the strength of the paste itself became significant.

In graph 2 the "interval of the difference between "means" vs. "stress" was plotted. The observations made from this graph were as follows:
a) At stresses of approximately 5000 psi the interval of the difference of the means calculated showed a magnitude of $0-15$ per cent increase. This increase indicates that at high stresses the crushed aggregate would increase the strength of concrete by that percentage over uncrushed.
b) At low stresses (approximately 3000 psi) the interval of the difference of the means span a length of -4 to 5 per cent. This means that at low stresses the difference between the use of crushed or uncrushed aggregate is relatively minimal.

In graph 3 the "difference between mean value and individual specimen stress in each group" vs. "stress" was plotted. From this graph it can be also verified'that at high stresses the use of the crushed gravel can provide a considerable advantage in concrete strength. As can be seen the horizontal span (stress variation) between the respective groups in each set increases as stress increases. The length of the horizontal span between the two groups of each set indicates the advantage of crushed over the uncrushed at a particular stress interval.

In graph 4 the "probability of a larger value" vs. "stress" was plotted using the method of least squares. The probability values plotted on this graph were obtained through the use of the t-distribution values from pg: 33 along with Table $B$ in the Appendix:From this graph it can be seen that at stresses exceeding 4500 psi there is almost a 100 per cent probability that the use of crushed aggregate will give a higher concrete strength over uncrushed. This probability decreases to 55 percent as stresses go below 4500 psi.

Generally, the benefit from using the crushed aggregate over crushed becomes most significant at higher levels of stress - 4500 psi and higher.

The following conclusions apply to concretes containing either crushed or uncrushed gravel and Portland Cement Type I.

The strength of the concrete made with crushed gravel exceeds the one made with uncrushed. Furthermore, this higher strength from the crushed gravel varies with the water/cement ratio. Generally as the w/c ratio increases,
a) The difference between the mean values decreases.
b) The interval of the difference between means using 95\% confidence level decreases.
c) The probability of the crushed gravel to have a higher stress than uncrushed decreases.

These conclusions are based on admittedly limited testing. Hence, some additional research should be carried out in order to determine how strength differences in concrete vary with a) aggregate (percent) content b) aggregate type c) time of testing d) cement type and e) cement (percent) content.
